# Outline of the presentation

- The Model - Choice of Domain
- The forecast system
- The assimilation system
- System evaluation
- Conclusions

## Choice of the domains

**Small domain: rotated Lambert pr.  
Dx=dy= 11 km, 60 vertical levels  
up to 0.2 hPa**

**Big domain: polar stereographic pr.  
Dx=dy= 16 km, 60 vertical levels  
up to 0.2 hPa**

# The forecast system

The CY31 was tested during one month:

→ First run using ECMWF analysis as initial file:

→ ECMWF as coupling files

- At the beginning we observed problem related to orography in the coupling files

- Larger bias near the surface

Surface blending did not help too much

## Type of observations

### Conventional Observations

- Surface data:
  - Synop, Ship
  - Bathy, Tesac
  - Buoy
- Upperair data:
  - Airep, Amdar, Acar
  - Temp, Temp-ship, Temp-mobil, Temp-drop
  - Pilot, Pilot-ship, Europrofil, Profiler
  - Satob, Satgeo, geowind (METEOSAT and MODIS)

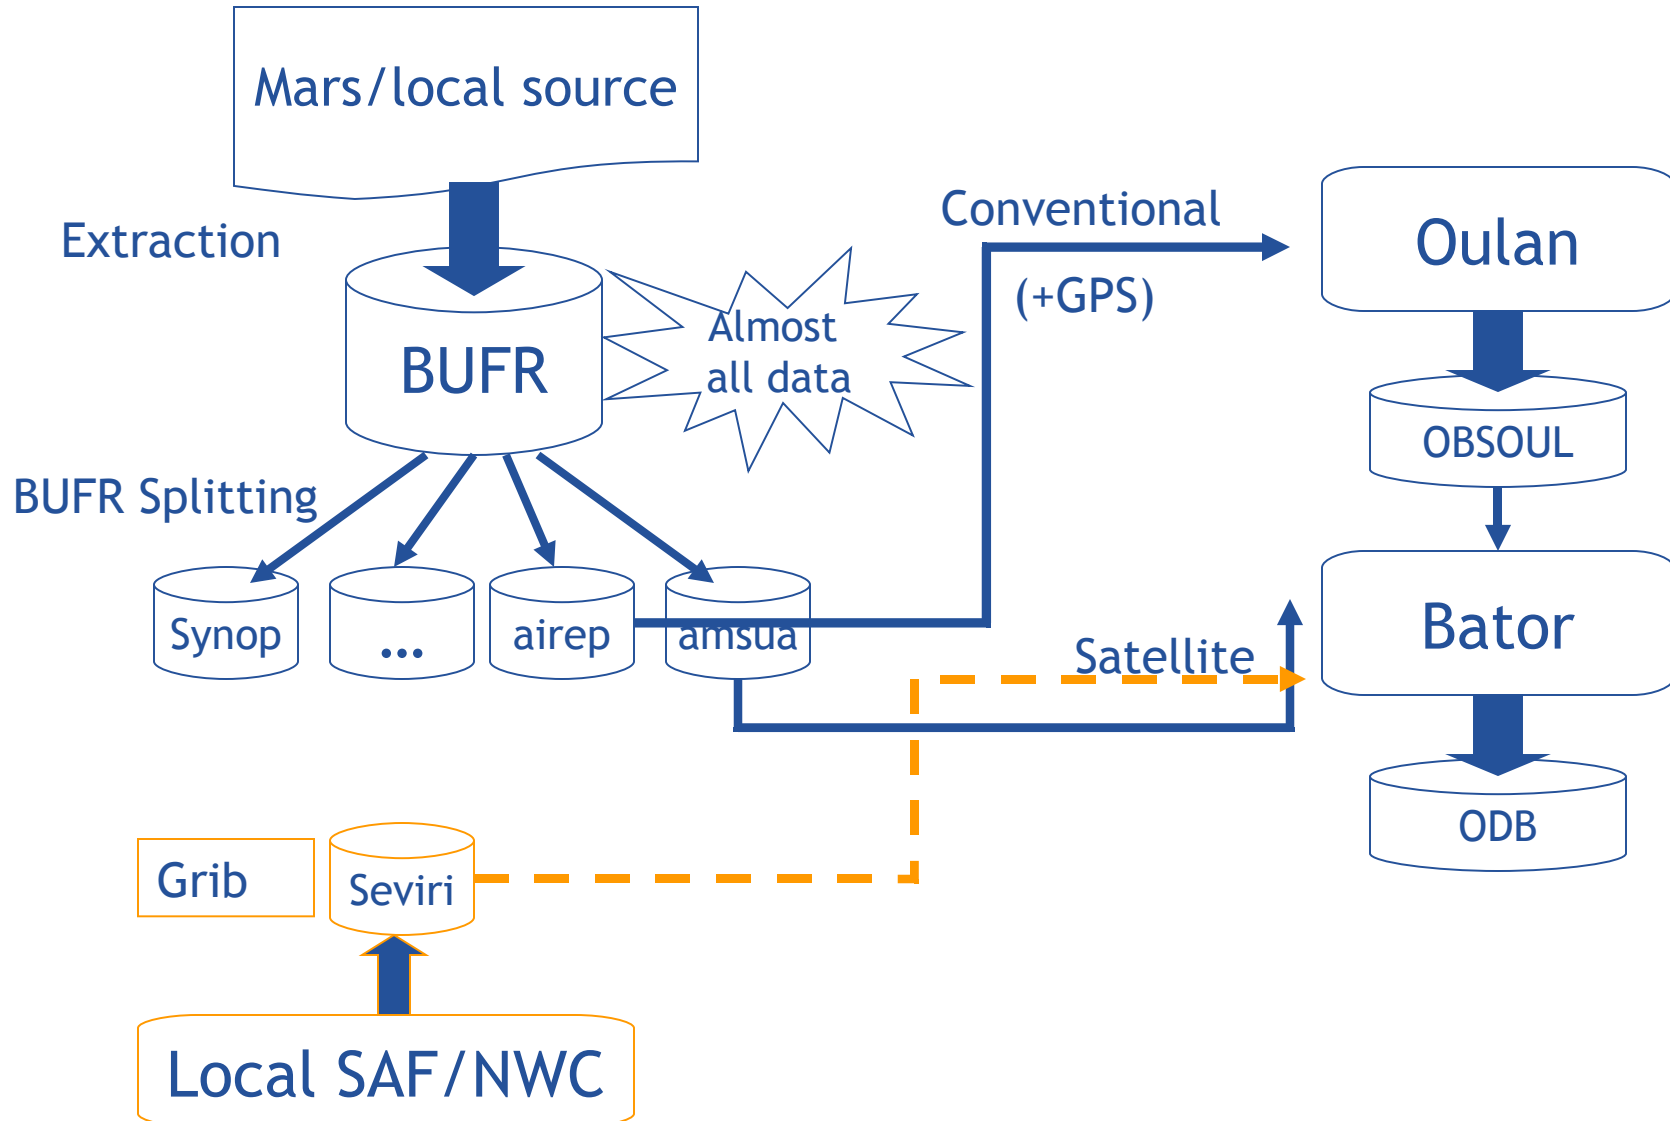

### Satellite Observations

- Meteosat:
  - SEVIRI
- NOAA Atovs:
  - Hirs, Amsua, Amsub, Mhs
- DMSP:
  - Ssm/I
- AQUA:
  - Airs
- Metop:
  - Amsua, Amsub, Mhs, Iasi
- GPS:
  - ZTD

# The assimilation system

## Data pre-processing

## Radiance bias correction

Off-line method (Harris and Kelly, 2001) :

For ATOVS: → Bias varying along latitude bands

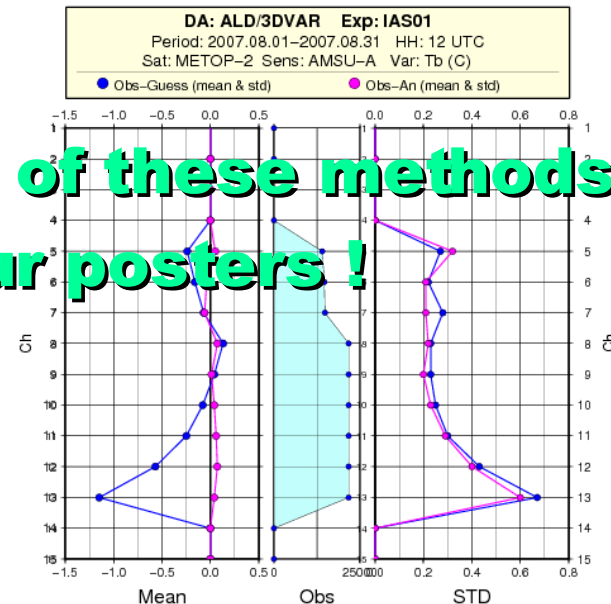

For Seviri: → Bias is estimated in one band for wall domain

Variational bias correction (Auligné et al, 2007):

Tested for ATOVS and IASI data

Off-line bias correction

Variational bias correction

**About the comparison of these methods**  
→ **See one of our posters !**

# The assimilation system

## NMC background error statistics

For the small domain:

- Two matrices were estimated using winter and summer periods

For the large domain:

- So far, one matrix was estimated using summer periods

For e

Winter Small

Summer Large

# The assimilation system

## System evaluation

### Impact of CANARI:

- Old analysis (black)
- New analysis with CANARI (blue)

# The assimilation system

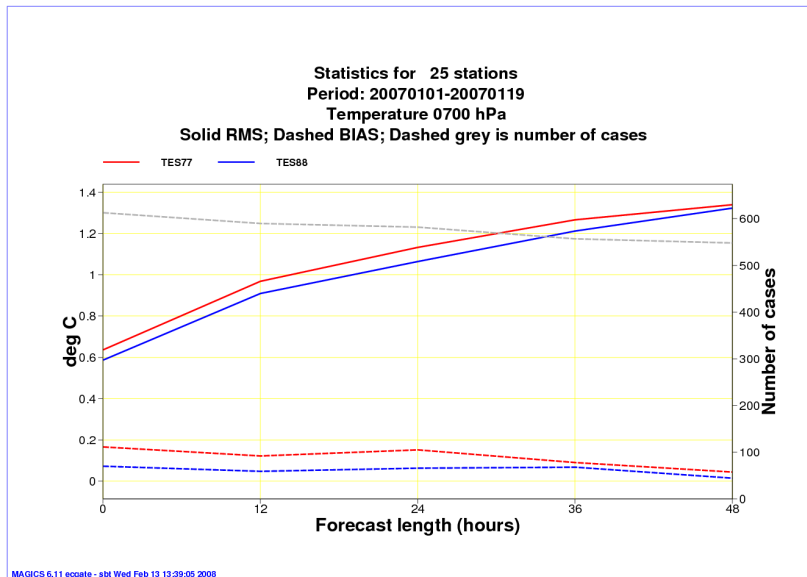

## System evaluation

NMC seasonal B tested during winter

→ Better analyses and forecast with Wint. B

- Run with summer B (red)
- Run with winter B (blue)

# Impact of observations on analysis

- **Degrees of Freedom for Signal (DFS)** evaluate the sensitivity of the analysis (in observations space) with respect to the observations, for each observation group, i.e. the information content of the observations brought into the analysis;

$$DFS_i = \frac{\partial Hx_a}{\partial y_i} \approx (y_i - \tilde{y}_i) R^{-1} (Hx_a - H\tilde{x}_a)$$

- It is calculated out by perturbing all the observations and studying the respective variation of the analysis in observation space. Such a procedure has to be repeated a number of assimilation cycles in order to ensure ergodicity and represent different meteorological situations and observations dataset. Perturbation must be done after screening to keep the same observations dataset in both minimizations.
- A winter NMC-based B has been used.
- We have results of 5 assimilation cycles (4 days and 6 hours distant each other).

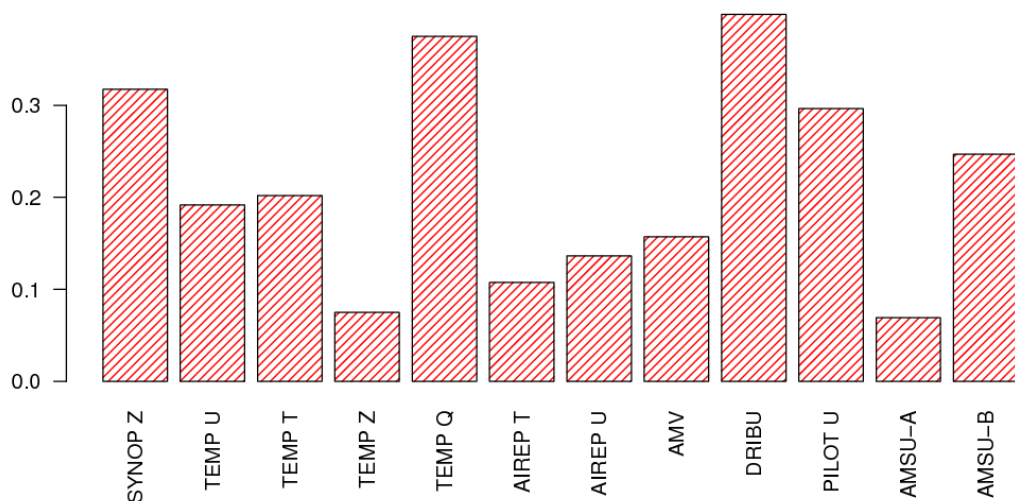

## Impact of observations on analysis

Absolute Degree of Freedom for Signal (DFS)

Relative Degree of Freedom for Signal (DFS/observations)

The ABSOLUTE value is the actual impact (a sort of index of amount and importance of obs) in the observing system, while the RELATIVE value gives the idea of importance of 'single observations'.

AIREP-U, AMSU-A and B, are the obs with the biggest impact. Datum on DRIBU: only very very few in areas not-densely observed.

# Impact of observations on forecasts

Evaluation of the impact of observations is made by perturbing observations, and defining a proper cost function to evaluate the sensitivity and the change in quality of forecasts:

$$SOF_i = \frac{\partial J}{\partial x_a} \cdot \frac{\partial x_a}{\partial y_i} = \frac{\partial J}{\partial y_i}$$

As cost function, the variation of RMSE of forecasts against analysis valid at same time with respect of RMSE of reference experiment (the one with all the observations unperturbed);

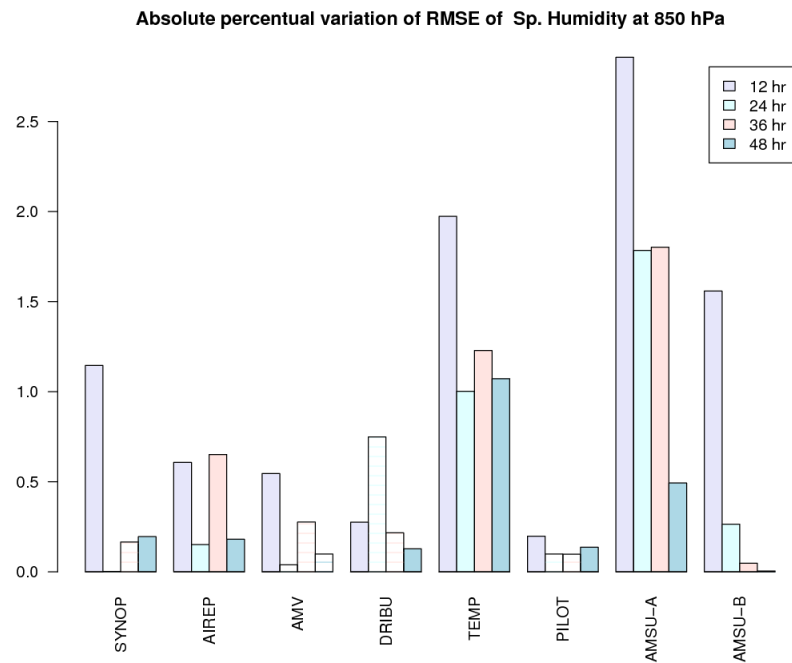

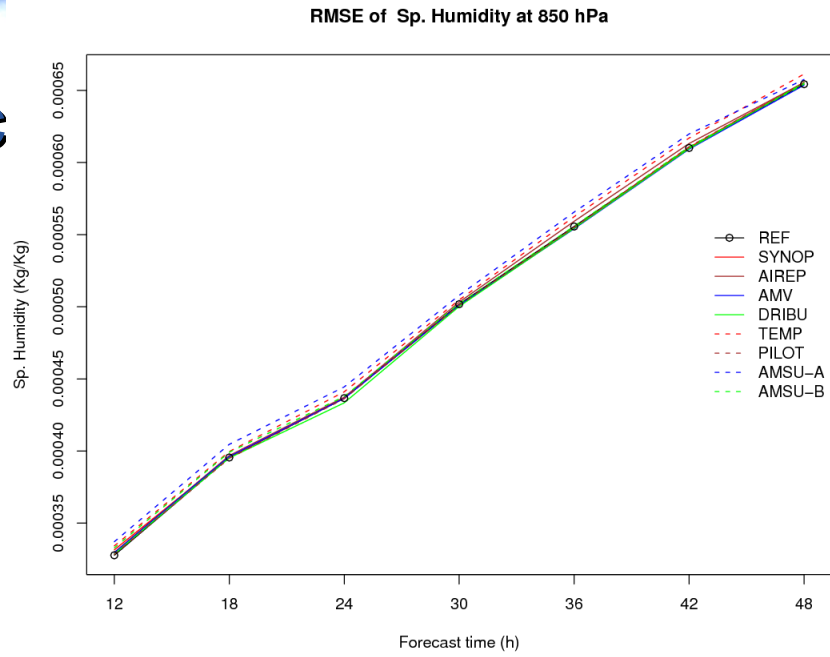

$$J = \frac{\overline{RMSE}_i - RMSE_{ref}}{RMSE_{ref}}$$

This is done **in practice perturbing all the observations of a group**, rerunning 3DVAR and forecasts as many times as the observations groups to evaluate: simplified way of study the impact of observations trough ensemble analysis.

- Number of assimilation+forecasts cycles has to be large enough (**now only with 4 cases**);
- **Expensive method, but much cheaper than OSEs**; the use of “variation of RMSE” provides an indication of both impact on forecasted fields (the analysis from which RMSE are computed are the same for all obs groups) and quality (**the bigger the RMSE variation, the more positive impact that observation group has on the forecasts**);

# Impact

# casts

# Concluding remarks

- Good and flexible script system was created for running different configurations/steps of the analysis and forecast system.
- We built a preprocessor (oulan) working with BUFR format.
- We showed the importance of the seasonal background error statistics.
- We evaluated the sensitivity of the analysis system to different type of observations using DFS.
  - Importance of 'single observations'.
  - AIREP, AMSU-A, AMSU-B/MHS and TEMP have the biggest impact.
- SOF - AMSU-A have the biggest impact on the forecasts for almost all the parameters, followed by TEMP, whose impact is very strong in the high atmosphere. AIREP observations seem very important for short-range forecasts, especially for temperature fields, while AMSU-B influences mostly for low and high level humidity
- Please, do not forget to visit our posters
  - Assimilation of superobs derived from CloudSat cloud measurements.
  - Assimilation of Zenith Total Delay data from GPS measurements.
  - Development related to the assimilation of IASI data.

**Thank you for your attention!**
