

Test of enhanced soil type determination in

Kai Sattler

— Danish Meteorological Institute — ksa@dmi.dk

Introduction & Motivation

The HIRLAM climate generation includes processing of soil type (Bringfelt et al. 1995), and the data base it refers to is taken from the FAO-UNESCO soil database (FAO-UNESCO, 1987). This soil data classifies soil types into 10 categories:

- | | |
|----------------|------------------|
| 1. sand | 6. loam & clay |
| 2. loam | 7. peat |
| 3. clay | 8. ice |
| 4. sand & loam | 9. rock |
| 5. sand & clay | 10. missing data |

The ISBA surface scheme in HIRLAM, however, does not make use of these 10 categories. Instead the ISBA preparation code for the climate files (steered by script Preps_ISBA) includes a remapping of the FAO soil types to 3 classes, which are a sub-set of the ISBA soil types (Bringfelt 1996, table A2.1). The three `soili` types are:

- 1. sand
- 5. loam
- 11. clay

They make up the sub-surface soil type `soili` used in HIRLAM (Bringfelt 1996, table A2.2). The representation of snow surface (SN) is hereby not used in recent HIRLAM versions.

Even though the remapping of the soil types and reduction to only three categories is a significant simplification, the procedure has worked reasonably well.

One reason for this is that the three classes are good repre-

sentatives of the soil characteristics. `sand` (1) and `clay` (11) represent two extremes, whereas `loam` (5) represents medium.

However, the limitations of the implemented soil type re-mapping became clear some years ago during spring time in the western part of Denmark, when HIRLAM's 2m temperature forecasts were found to grow too much during daytime compared to the observed values.

A significant contribution to this effect was found to come from the lack of soil water content, which in turn was found to be connected to the definition of the soil type in the `low vegetation` sub-surface tile of the HIRLAM grid, e.g. soil moisture initialization during a cold start depends strongly on the underlying soil type.

A large part of western Denmark (Jutland) was hereby found to be classified by soil type sand. Even though this soil type occurs at coastal locations, it cannot be seen as a major soil type over the area. The FAO soil type data base does not supply these details.

An experiment was then performed, where the soil type was set to `loam` instead of `sand`, in order to make HIRLAM see a medium soil type with medium soil water capabilities. The experiment showed an improvement of T2m by 1 to 2 degrees locally in Jutland. A quick fix was then applied in operational DMI-HIRLAM.

Refining soil type determination

Recently the issue of soil type definition for HIRLAM ISBA scheme was taken up again, when extreme surface temperatures were observed at the coast of Greenland. Even though these problems had other causes and were not related, they revealed a code bug concerning the **no vegetation** sub-surface tile. As a consequence, the potential insufficiencies of soil type definitions in the other two sub-surface tiles **low vegetation** and **forest** were discussed. These discussions took up the idea to refine the soil type determination by utilizing the sub-surface type **vegi** in addition to the FAO soil type not only under sub-surface tile **no vegetation**, but also under **low vegetation** and **forest** (As Table A2.2 in Bringfelt (1996) shows, **vegi** has been utilized in tile 3, but not in tiles 4 and 5).

The combination of using **vegi** and **FAO soil type** has the potential to refine the ISBA soil type determination, because the vegetation type may give an indication on the underlying soil type. This way the crude information on soil type in the FAO data can be enhanced by making use of information about the vegetation.

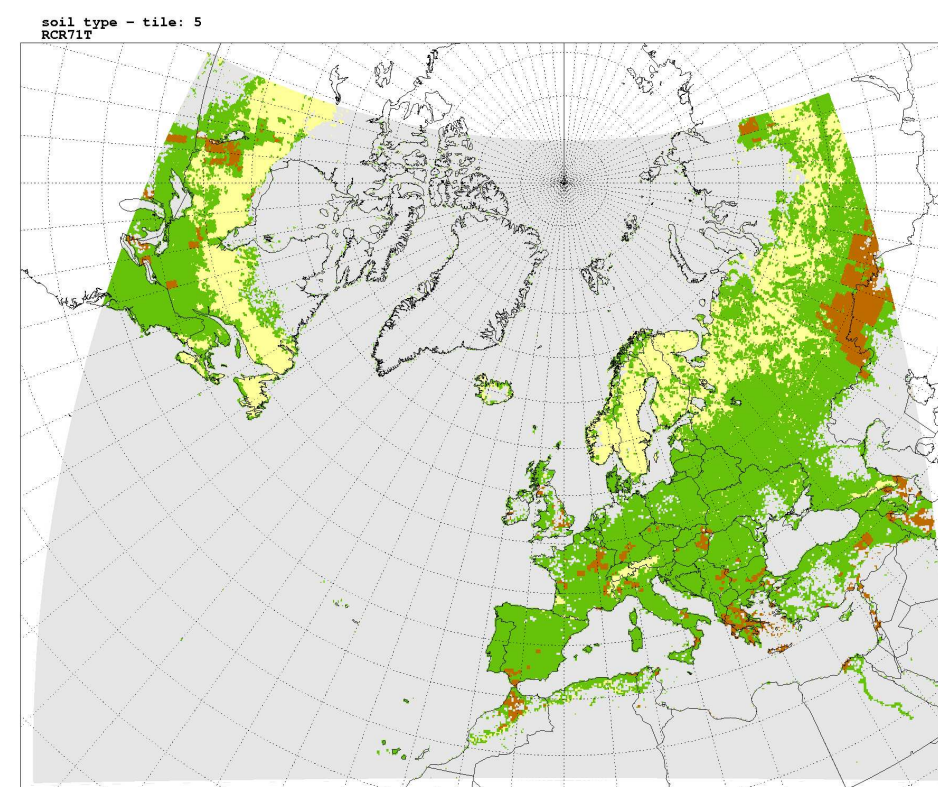

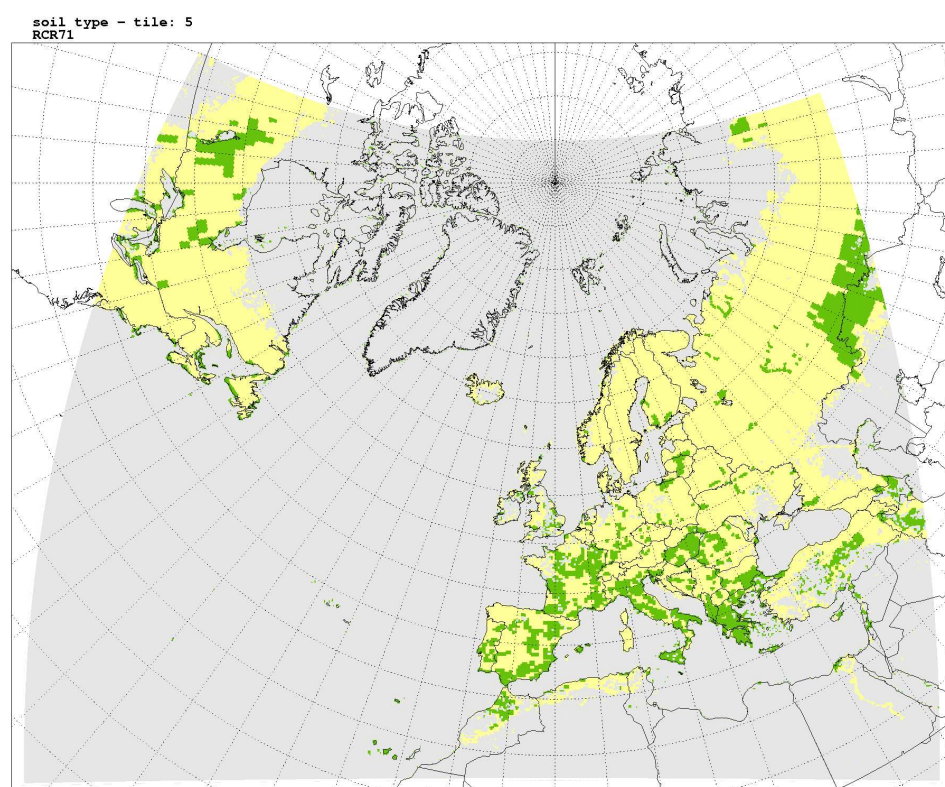

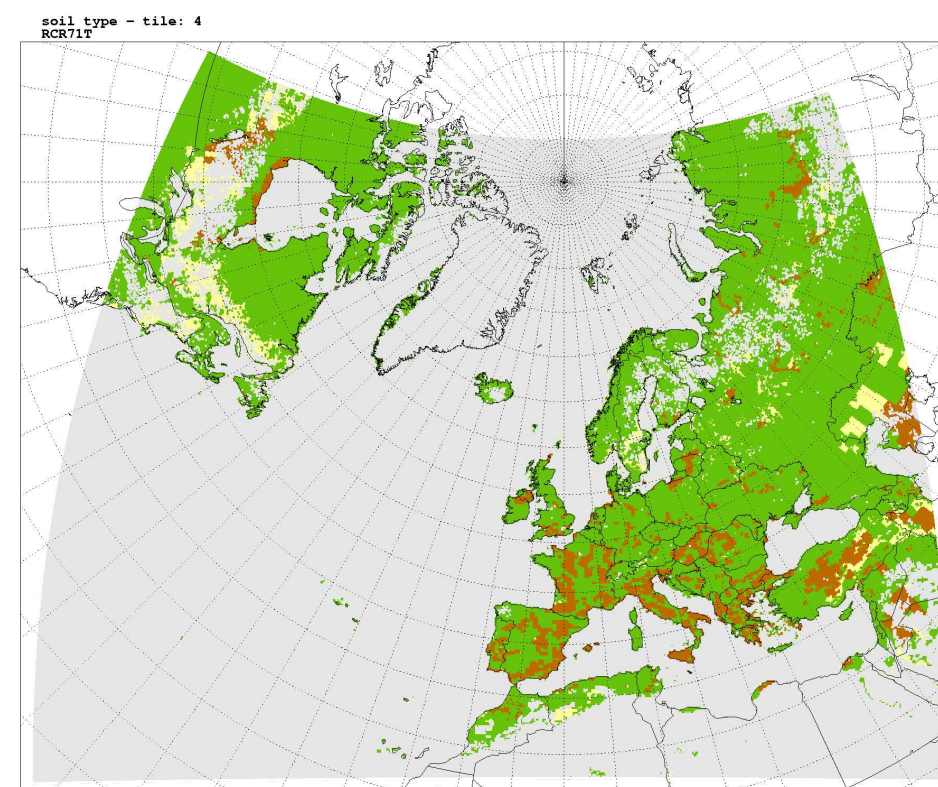

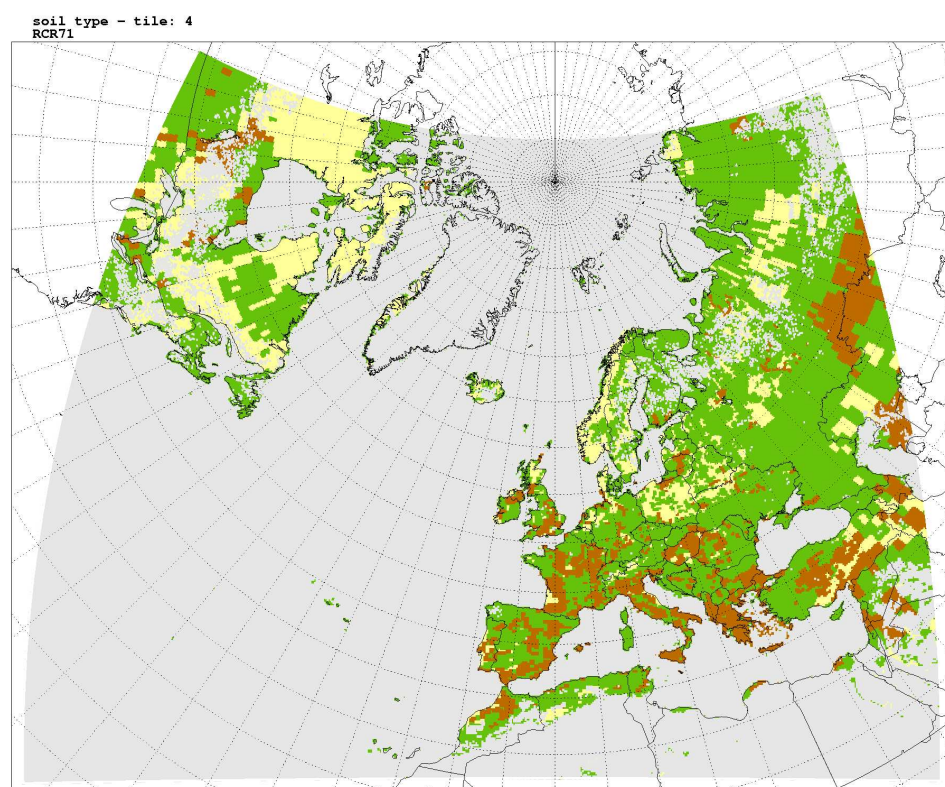

The new mapping of FAO soil type and **vegi** into ISBA sub-surface soil type is formulated in the list to the right, for each of the three sub-surface tiles **no vegetation** (3), **low vegetation** (4) and **forest** (5):

FAO soil type	1	4,7	2,6	5	3	8	9	0
Tile 3 no vegetation								
vegi = 8 (desert)	1	1	1	1	1	5	1	1
vegi = 12 (ice)	5	5	5	5	5	5	5	5
Tile 4 low vegetation								
vegi = 1 (crop)	5	5	5	5	11	5	5	5
vegi = 2 (short grass)	1	5	5	11	11	5	1	5
vegi = 7 (tall grass)	1	5	5	11	11	5	1	5
vegi = 9 (tundra)	5	5	5	5	11	5	5	5
vegi = 10 (irrigated crop)	1	5	5	11	11	5	1	5
vegi = 11 (semi-desert)	1	5	5	11	11	5	1	5
vegi = 13 (bog/marsh)	5	5	11	11	11	5	5	11
vegi = 16 (evergreen shrub)	5	5	5	5	11	5	5	5
vegi = 17 (deciduous shrub)	5	5	5	5	11	5	5	5
Tile 5 forest								
vegi = 3 (evergreen needle tree)	1	1	1	5	5	5	1	5
vegi = 4 (deciduous needle tree)	1	1	1	5	5	5	1	5
vegi = 5 (deciduous broadleaf tree)	5	5	5	5	11	5	5	5
vegi = 6 (evergreen broadleaf tree)	5	5	5	5	11	5	5	5
vegi = 18 (mixed woodland)	5	5	5	5	11	5	5	5
vegi = 19 (forest/fields)	5	5	5	5	11	5	5	5

The difference between the current and the new ISBA soil type determination in HIRLAM can be seen from the pictures below.

current

new

Impact on surface parameters

Overall scores

The impact of the refinement of ISBA soil type determination `soili` was tested in two experiments. The first experiment made use of the soil types as in the current HIRLAM system, and the second one used the newly defined soil types as described above.

Both experiments were run over the following three periods:

1. 2007-02-10 to 2007-02-28
2. 2007-04-01 to 2007-04-30
3. 2007-06-20 to 2007-07-20

The first period is to represent winter conditions, and the second period includes shifting weather condition, which include sunny high pressure situations over Europe. The third period contains a summer period with many thunderstorms.

Both experiments are based on HIRLAM trunk version as of changeset [5673], still including the fix of changeset [5692]. The experiments were configured to run on the RCR-7.1 domain, and using 3DVAR analysis. Else default specifications were used.

HIRLAM standard verification was applied to the experiment runs. Overall impact of the `soili` refinement on surface parameters `MSLP`, `T2m`, `RH2m` and `W10m` is shown in the following figures (EWGLAM station list).

Verification against observations EXP: RCR71 RCR71T

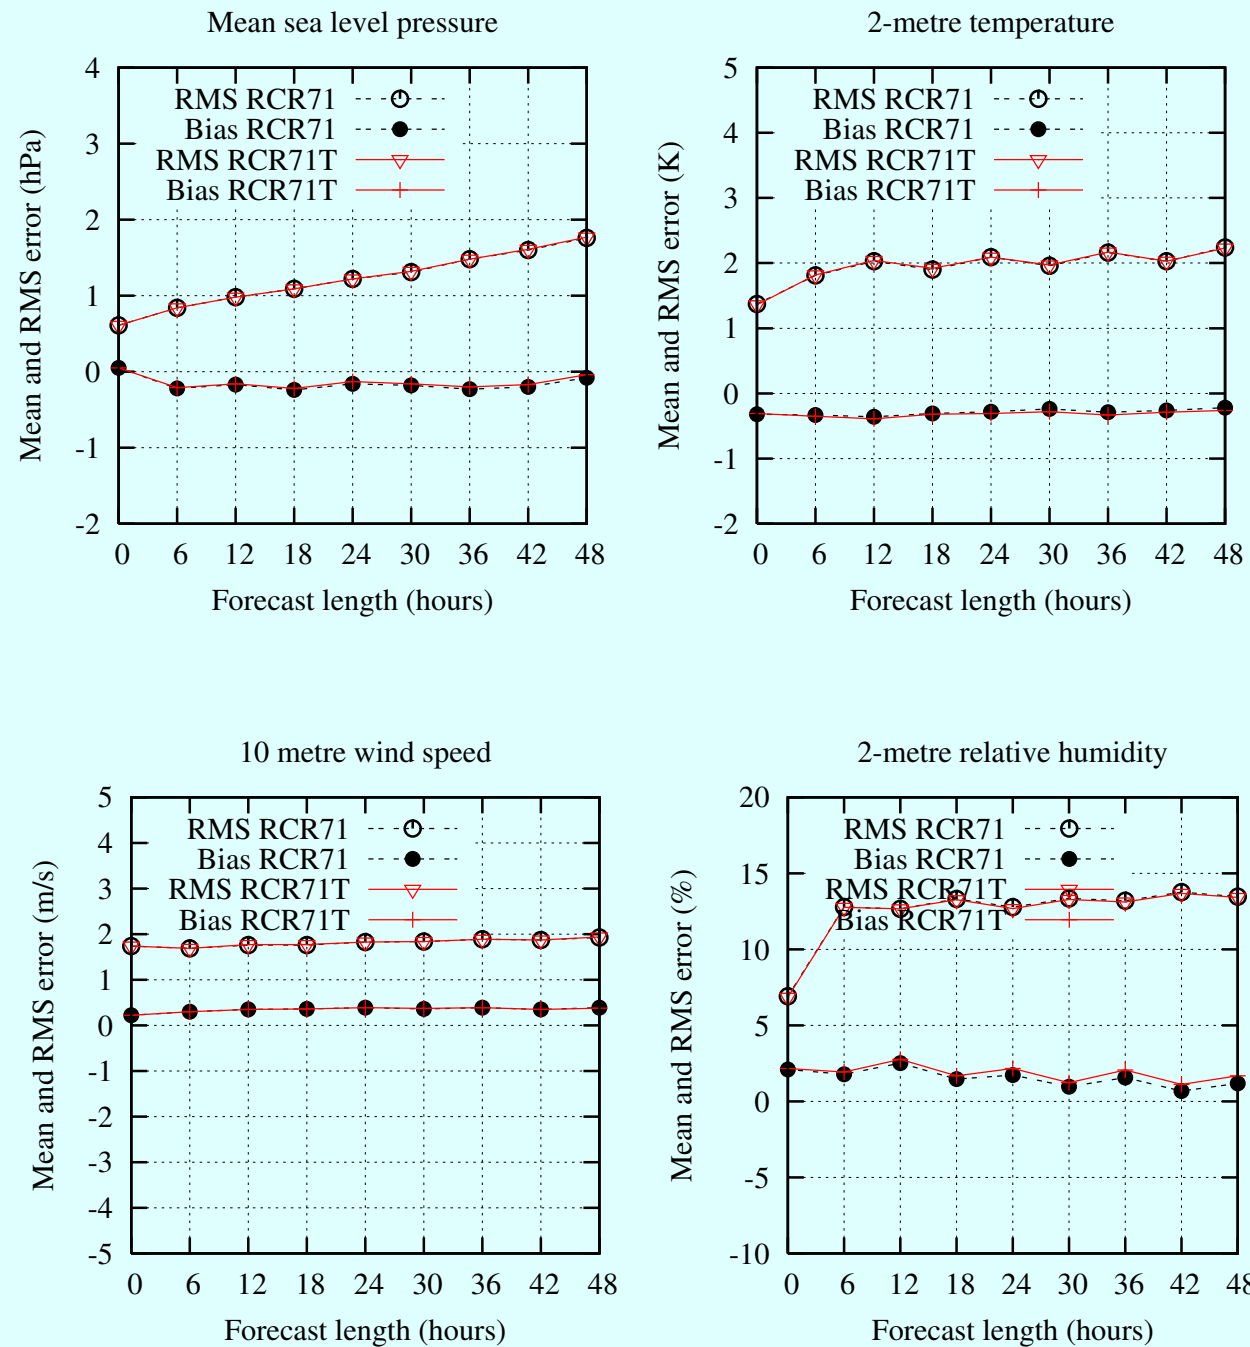

Time: 2007021012 - 2007022812 Domain: EWG Forecast from 00 12

Impact on surface parameters

Verification against observations EXP: RCR71 RCR71T

Time: 2007040112 - 2007043012 Domain: EWG Forecast from 00 12

Verification against observations EXP: RCR71 RCR71T

Time: 2007062012 - 2007072012 Domain: EWG Forecast from 00 12

As the figures above show the impact of the refined determination of [soili](#) on surface parameters is very small. The new definitions have slight tendency to higher 2m humidity, and in accordance to this, a slight tendency to lower 2m temperature. When considering the model bias for T2m and

RH2m, these tendencies seem to be rather counter-productive, however. There is no visible impact on 10m wind speed. For mean sea level pressure, a very small improvement of the negative bias in the April period is visible (upper left figure of the left panel on this sheet).

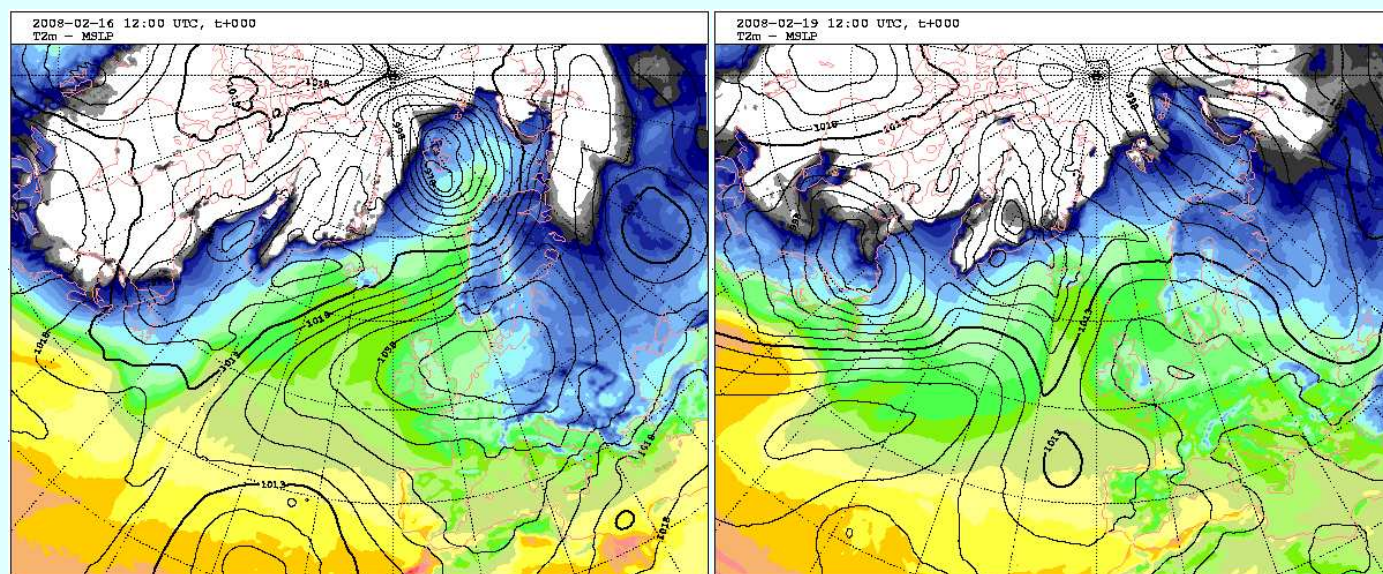

Impact on surface parameters

Time series

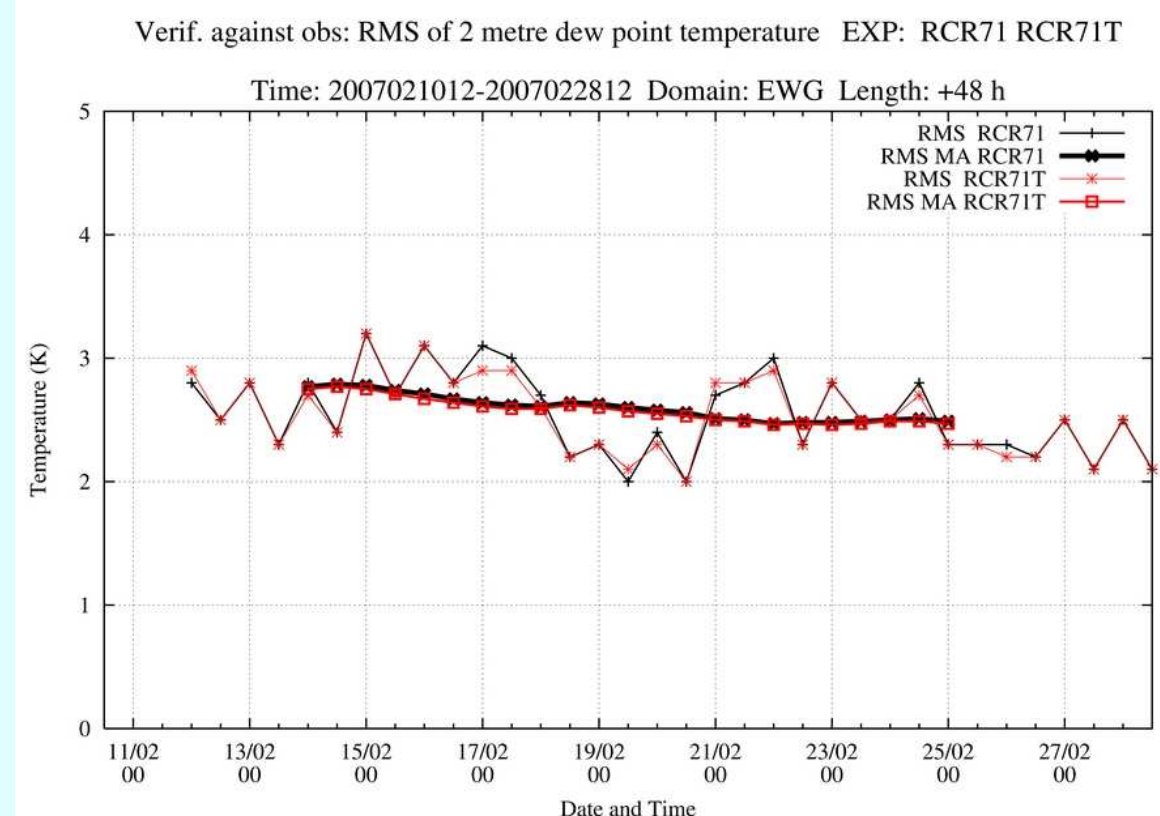

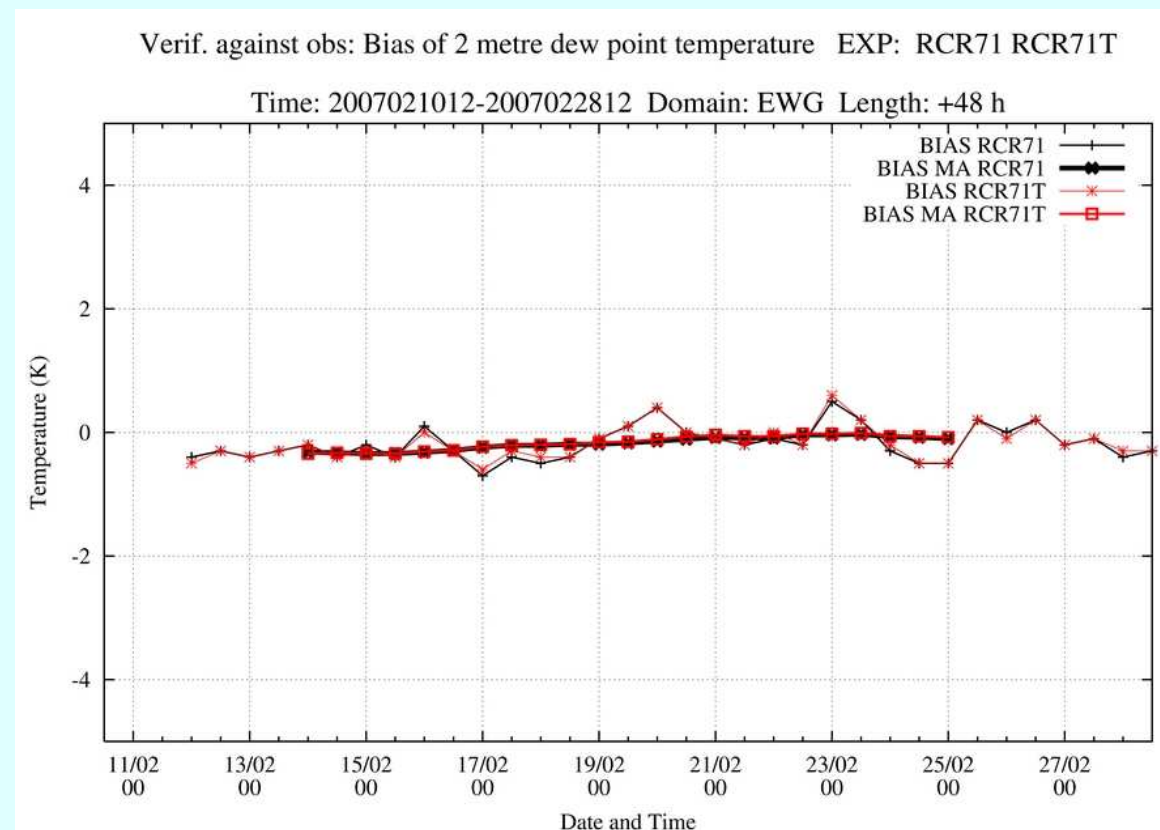

A look at the time evolution of the verification scores confirms the slight impact almost at all times. Respective figures are shown for the 2m dew point to the right and further below (bias and rms).

The dew point parameter experiences the biggest influence, but still it is a very small one.

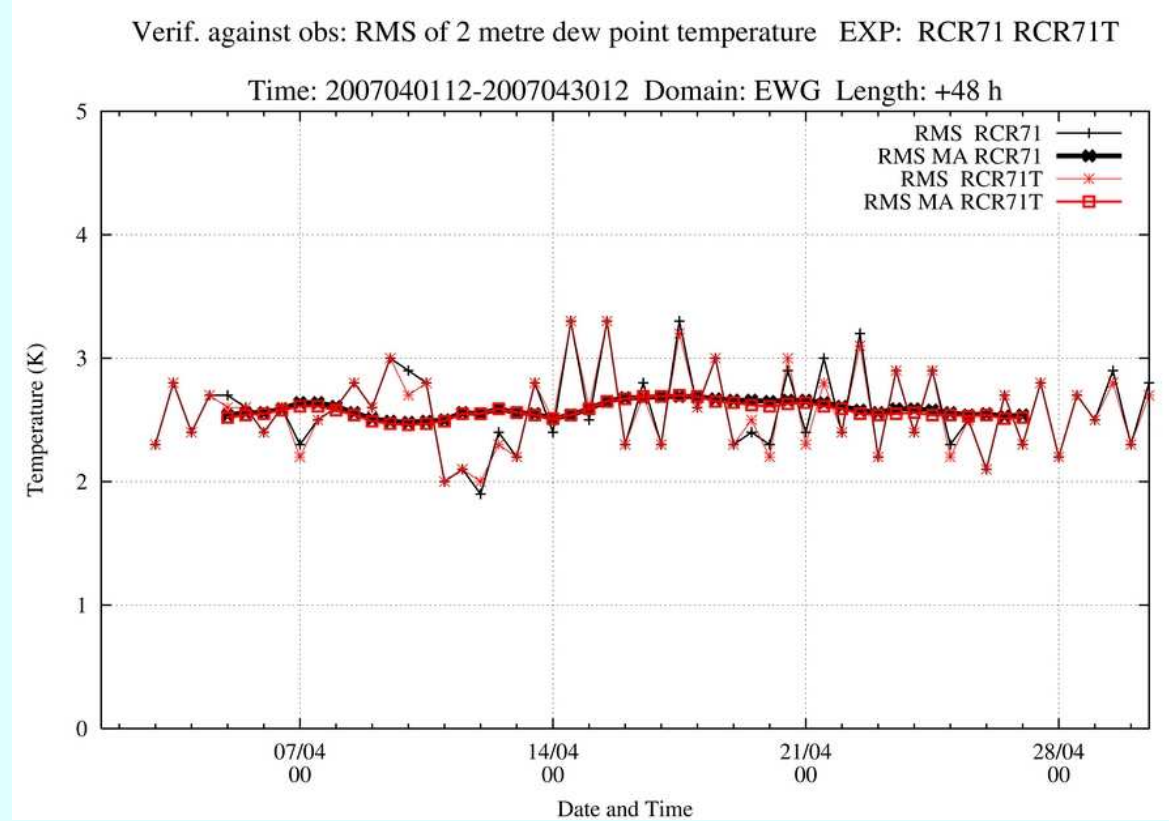

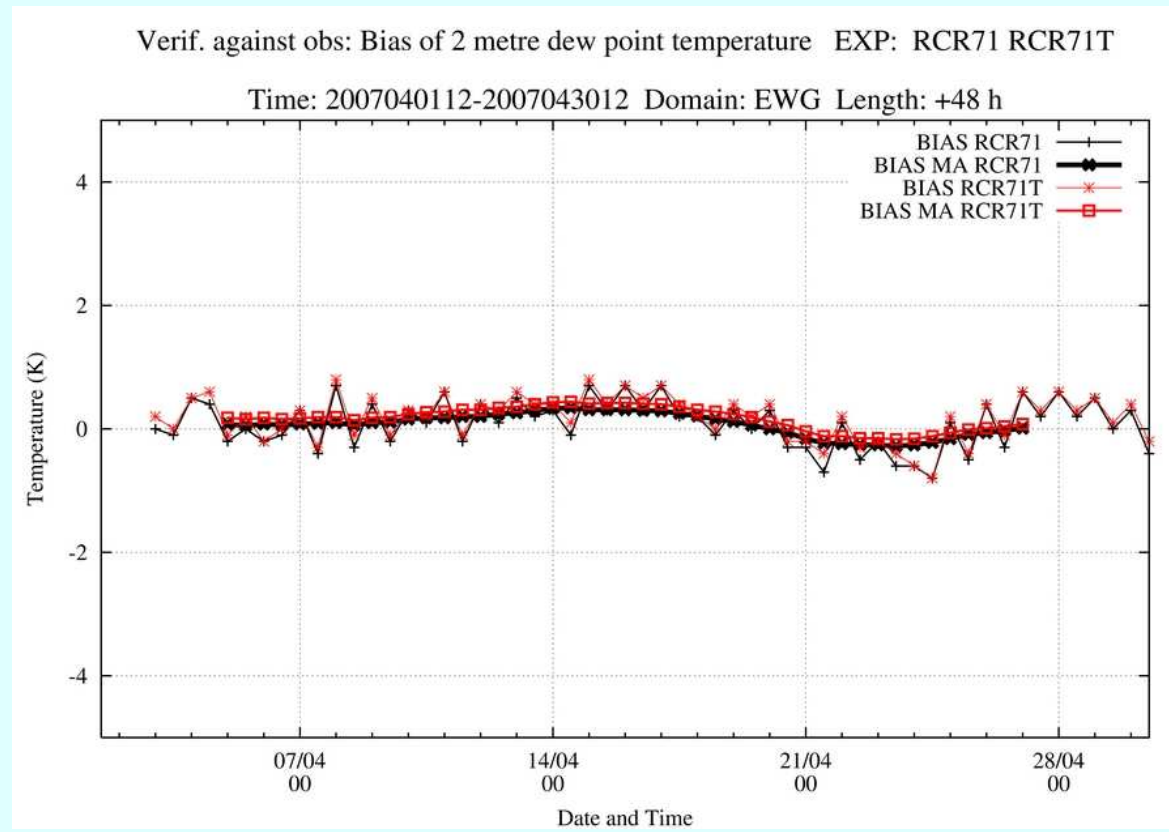

An exception is a short period around the 17th and 18th of February 2007, where the refined `soili` settings have a visible **positive impact** on the RMS of the dew point (see lower figure to the right). The period between 16th and 19th of February was characterized by a warming over the European continent, especially the eastern and some of the northern parts. The following two maps of 2 metre temperature illustrate this:

2m temperature and mean sea level pressure at 16th and 19th February 2007

Impact on surface parameters

Impact on surface parameters

Spatial distribution

The verification scores of the surface parameters **MSLP**, **T2m**, **RH2m** and **W10m** compare very similarly between the two experiments, when regarding the stationwise scores from the two HIRLAM experiments. The following figures show the distributions of **bias** (panels to the left) and **rms** scores (panels to the right) valid for 48h forecast length. The experiments shown are:

RCR71.

used the current **soili** settings in HIRLAM shown on the left hand side of each panel respectively

RCR71T.

used the refined **soili** settings shown on the right hand side of each panel respectively

Each row in a panel refers to one of the three periods.

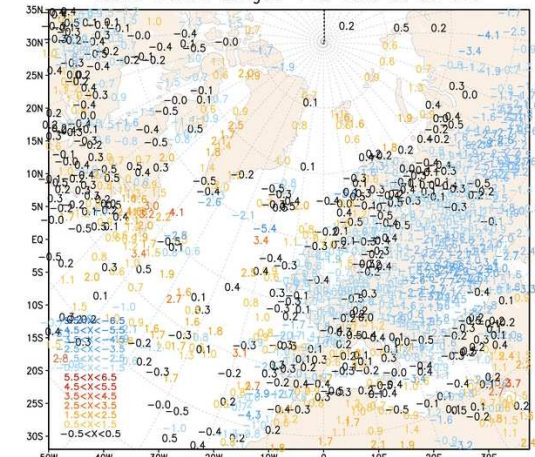

The figures show that small local differences occur, usually with improvements in one region and deterioration at another location at the same time.

It is interesting to notice, still, that differences also occur over the open sea. This may indicate that the differences of surface parameter scores induced by the change in **soili** fields over land tiles have propagated through the model domain within the time period of the forecast range.

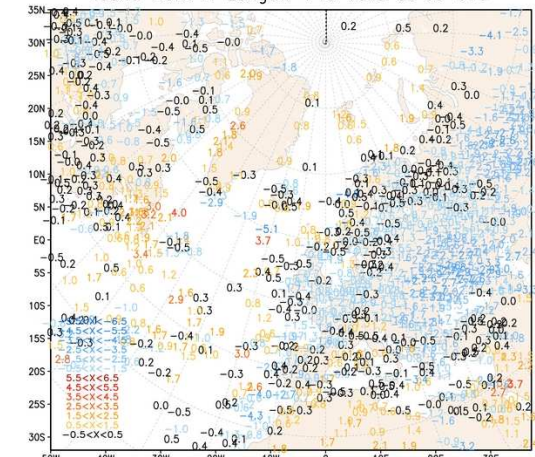

So the effect of changing **soili** does not remain a local one, but it spreads over the model domain within the usual forecast range. It can also be expected that the effect has (small) impact on the daily cycle in an operational setup of HIRLAM.

Summary and Conclusions

This work tries to investigate the effect of changing the ISBA soil type fields (**soili**) in HIRLAM on the verification scores of surface parameters **mean sea level pressure**, **2m temperature**, **2m humidity** and **10m wind speed**.

The new **soili** fields are based on a refined determination of the soil type. This refinement takes both the **FAO soil type** as well as the sub-surface type **vegi** into account when defining one of the three ISBA soil types for a certain land tile of the HIRLAM grid. This methodology has been in use for the sub-grid surface tile 3 (**no vegetation land**) since the ISBA scheme was introduced into HIRLAM, but it was never applied for the sub-grid surface tiles 4 (**low vegetation land**) and 5 (**forest**).

The refined methodology was compared to the current procedure in HIRLAM by running HIRLAM experiments for three periods of several weeks duration each. The periods represent **winter** season, **spring** and **summer** conditions. The comparison comprises **standard verification scores** for the surface parameters mentioned above.

Results show that refining the **soili** determination in HIRLAM has a small effect on the verification scores. This effect consists mainly in the tendency towards slightly increased humidity and slightly decreased temperature close to the surface.

In cases where the temperature bias of HIRLAM is negative, or where humidity bias is positive, the refinement of **soili** has a rather negative influence.

In the same way, in case of positive temperature bias, or negative humidity bias in HIRLAM, the **soili** refinement has a slight positive effect.

The spring case also indicates a slight improvement of mean sea level pressure bias.

Local differences in scores occur, as well as there are local differences in bias scores, so the effect of the **soili** refinement changes from region to region. An improvement of verification scores for surface parameters due to **soili** refinement can therefore hardly be stated in general.

A **single case** within the first comparison period indicates, however, an **improved rms** in dew point during some days of the winter period.
